1 Introduction

Genetic algorithms are a biologically-inspired approach to heuristic search which mimic natural selection. Unlike many other evolutionary strategies and evolutionary programming, they are not designed to solve a specific problem, but are designed to solve the problem of optimisation which is made difficult by substantial complexity and uncertainty[1].

The complexity of the task should make it such that discovering an optimum solution is a long, maybe even impossible, task. At the same time the uncertainty needs to be reduced so that the knowledge of *available* options can be increased.

The initial design for a genetic algorithm was a method for moving from one population of chromosomes to another using a form of natural selection. This algorithm also included methods for crossover, mutation and inversion. This idea of having a large population was the distinguishing feature from any past attempts which had only considered the parent and one offspring, where the offspring was simply a mutation of the parent[2].

1.1 Evolutionary Algorithms

As their name suggests, an evolutionary algorithm applies elements from the biological theory of evolution to the problem of optimisation. These elements include:

- Reproduction
- Mutation
- Recombination
- Selection

Typically, a population of candidate solutions are generated to which a fitness function can be applied. The population is then subject to some form of evolution, and this process is repeated until a halting criteria is met.

Genetic algorithms are a type of evolutionary algorithm with a focus on the genetic evolution of solutions. Candidate solutions for genetic algorithms, known as *chromosomes* are encoded as a series of *genes*. These genes are a representation of the choices which need to be optimised for the solution and can be as simple as a single bit or as complex as a real number, depending on the problem.

There are many other forms of both evolutionary and genetic algorithms which this report will mention in later sections.

2 Basic Genetic Algorithm Principals

The basic principals of genetic algorithms are to represent candidate solutions as a population of chromosomes, from this population the fittest members can be picked out and used in the next generation and to create new member of the population through reproduction and/or mutation.

This cycle repeats with the aim to produce better performing individuals in each generation until the optimum solution is either reached or gotten close enough to that any future improvement is unnecessary or unwanted due to other constraints such as processing time. The latter of these allows a genetic algorithm to come up with a “good” solution in a reasonable amount of time.

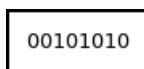

Reproduction and mutation are an important part of genetic programming, and too of evolutionary programming. Without these parts the algorithm would quickly reach a local optima for the initial population and would not improve past this.

2.1 Chromosome Representation

One of the key parts parts in implementing a genetic algorithm is the representation of chromosomes. This is very dependent of the problem the genetic algorithm needs to optimise and can have a knock on affect on the efficiency and accuracy of the algorithm.

Sometimes a simple solution is enough to represent the problem, binary strings are a commonly suggested approach. However sometimes more complex representations are required, potentially any data structure can be used as a chromosome but lists and trees are the common choices as they are easy to perform crossover¹ and mutation on.

As a very simple example, to maximise y in: $y = f(x)$, one could represent the value of x as a binary string, an example of which is shown in figure 1.
